

## Apparatus and Method for Generating Wander Noise

[30020678 US]

### Field of the Invention

**[0001]** This invention relates to an apparatus and a method for generating  
5 wander noise, particularly, though not exclusively, for producing wander noise  
that matches a predefined noise profile. The invention may be applied in the  
measurement of timing errors in digital transmission systems, for example,  
standardised measurement known as Timing Deviation (TDEV) in Synchronous  
Digital Hierarchy (SDH) digital transmission systems in accordance with  
10 specifications as set out by the ITU-T ("ITU" stands for International  
Telecommunications Union).

### Background of the Invention

**[0002]** Modern telecommunications networks demand a high degree of  
15 synchronisation between network transmission elements. For all network  
transmission elements in SDH architectures, timing is critical. However, phase  
variations in the reference clock frequencies governing synchronous network  
elements may introduce errors at various stages in the network.

**[0003]** Degradation of synchronisation in an SDH network may be due to  
20 several factors. Common causes include variations in propagation times in  
cabling and frequency drifts due to temperature changes in the Phase Locked  
Loops (PLLs) used. Errors in synchronisation may also occur if a  
Synchronisation Supply Unit (SSU) or SSDH Equipment Clock (SEC) operates  
out of the ideal locked mode and in hold-over or free-running modes. Any  
25 general re-configuration event in the synchronisation chain may give rise to  
transient events, as will a change of a Primary Reference Clock (PRC) in  
international links.

**[0004]** Variations in the timing signal may be broadly split into two categories.  
In the ITU specifications, short term variations which are of frequency greater  
30 than or equal to 10 Hz are referred to as "jitter". Longer term variations, which  
are of frequency less than 10 Hz, are referred to as "wander".

**[0005]** Since there are strict regulations governing timing it is necessary to  
have some means of measuring and identifying faults and errors. Three  
important measurements of network timing errors in the ITU recommendations

are the Time Interval Error (TIE), Maximum TIE (MTIE), and Time Deviation (TDEV). Of principal interest for the present invention is TDEV, which is a measure of the time variation of a signal over a specific integration time (observation interval). TDEV is measured in units of time and is derived from a sequence of Time Interval Error (TIE) samples. TDEV can provide information on the noise signal. TDEV values, together with other parameters, are used to evaluate the performance of equipment and systems, often to diagnose a fault which has developed and which impairs customer service.

**[0006]** In order to test the ability of a device to operate in a telecommunication network with noise present, a noise source signal can be injected into the device, which will emulate noise with a recommended characteristic. TDEV can be used as such a characteristic in order to test telecommunications networks. In order to do so, a wander noise signal having a particular frequency profile corresponding to the TDEV needs to be generated. Traditionally, methods of wander noise generation use a Pseudo Random Binary Sequence (PRBS), which produces an approximately white phase spectrum. A sequence generated by a PRBS is then filtered to produce a frequency spectrum that is a satisfactory approximation to the required TDEV wander noise profile.

## **20    Brief Summary of the Invention**

**[0007]** The present invention therefore seeks to provide a method and apparatus for generating wander noise, especially wander noise that matches a predefined profile, such as TDEV.

**[0008]** Accordingly, in a first aspect, the invention provides a method for generating wander noise according to a predefined frequency profile, the method comprising the steps of selecting one of a plurality of predefined frequency profiles, providing predetermined frequency, amplitude and phase values for each of a plurality of tones for the selected predefined frequency profile, generating a digital noise signal based on the sum of the plurality of tones, and generating a wander noise signal from the digital noise signal.

**[0009]** The method may further comprise the step of adding a centre frequency signal to the digital noise signal before the wander noise signal is generated.

**[0010]** In one embodiment, the predetermined frequency values for each of the plurality of tones are determined by the steps of defining a required frequency profile, determining a frequency range for the required frequency profile, the required frequency range having upper and lower frequency limits, 5 determining the plurality of tones required to provide a desired tone density in the determined frequency range, and determining frequency values for each of the plurality of tones.

**[0011]** The step of determining frequency values for each of the plurality of tones may comprise the step of determining a geometrical tone spacing 10 between the upper and lower frequency limits.

**[0012]** The predetermined amplitude values for each of the plurality of tones may be determined by the step of iteratively determining an amplitude value for each of the plurality of tones to produce a desired fit to the required frequency profile.

15 **[0013]** The predetermined phase values may be determined by the steps of applying a phase value for each of the plurality of tones, generating a digital noise signal based on the sum of the plurality of tones, and repeating the steps of applying a phase value and generating a digital noise signal until the digital noise signal produces a desired fit to the required frequency profile, whereby the 20 phase values that produce the digital noise signal that produces a desired fit to the required frequency profile are used as the predetermined phase values.

**[0014]** The desired fit of the digital noise signal to the required frequency profile may be determined by determining the skewness and kurtosis values for the plurality of tones and comparing the skewness and kurtosis values to 25 predetermined desired skewness and kurtosis values.

**[0015]** The predetermined frequency, amplitude and phase values are associated with the corresponding predefined frequency profile and may be stored in a memory.

30 **[0016]** According to a second aspect, the invention provides an apparatus for generating noise according to a predefined frequency profile, the apparatus comprising:

a memory for storing predetermined frequency, amplitude and phase values for each of a plurality of tones for each of a plurality of predefined frequency profiles;

a digital signal processor coupled to the memory for obtaining the predetermined frequency, amplitude and phase values for the plurality of tones for a selected one of the plurality of predefined profiles and for generating a digital noise signal based on a sum of the plurality of tones; and

5 a synthesizer coupled to the digital signal processor for receiving the digital noise signal and for generating a wander noise signal from the digital noise signal.

**[0017]** In one embodiment, the digital signal processor further includes means for adding a centre frequency signal to the digital noise signal.

10 **[0018]** The apparatus may include means for predetermining the frequency values for each of the plurality of tones for a required frequency profile by determining a frequency range for the required frequency profile, the required frequency range having upper and lower frequency limits, determining the plurality of tones required to provide a desired tone density in the determined  
15 frequency range, and determining frequency values for each of the plurality of tones.

**[0019]** The means for predetermining the frequency values may determine a geometrical tone spacing between the upper and lower frequency limits to produce the predetermined frequency values for each of the plurality of tones.

20 **[0020]** The apparatus may include means for predetermining the amplitude values for the plurality of tones by iteratively determining an amplitude value for each of the plurality of tones to produce a desired fit to the required frequency profile.

**[0021]** The apparatus may include means for predetermining the phase  
25 values for the plurality of tones by applying a phase value for each of the plurality of tones, generating a digital noise signal based on the sum of the plurality of tones, repeating the steps of applying a phase value and generating a digital noise signal until the digital noise signal produces a desired fit to the required frequency profile, whereby the phase values that produce the digital  
30 noise signal that produces a desired fit to the required frequency profile are used as the predetermined phase values.

**[0022]** The means for predetermining the phase values may include means for determining the skewness and kurtosis values for the plurality of tones and

comparing the skewness and kurtosis values to predetermined desired skewness and kurtosis values.

#### Brief Description of the Drawings

5 **[0023]** One embodiment of the invention will now be more fully described, by way of example, with reference to the drawings, of which:

FIG. 1 shows a typical frequency response of TDEV for a constant time interval;

FIG. 2 shows a typical time response of TDEV for a constant frequency;

10 FIG. 3 shows an example of an input TDEV characteristic profile varying with time as specified by the ITU;

FIG. 4 shows graphs of skewness and kurtosis for a noise signal wherein all the tones have a phase value of zero;

15 FIG. 5 shows graphs of skewness and kurtosis, similar to those of FIG. 4, but with the tones having phase values determined according to an embodiment of the invention;

FIG. 6 shows a schematic diagram of an apparatus for generating wander noise according to an embodiment of the present invention;

20 FIG. 7 shows the TDEV characteristic profile of FIG. 3 with a wander noise signal generated by the apparatus of FIG. 6 superimposed thereon; and

FIG. 8 shows a schematic flowchart of the method of generating wander noise according to an embodiment of the present invention.

#### Detailed Description of the Drawings

25 **[0024]** As is known, TDEV can be calculated from the phase difference between a clock signal and its ideal position in time. The phase difference is termed time interval error (TIE). TDEV may be calculated from TIE thus:

$$\text{TDEV}(\tau) = \sqrt{\frac{1}{6n^2(N-3n+1)} \sum_{j=1}^{N-3n+1} \left( \sum_{i=j}^{n+j-1} x_{i+2n} - 2x_{i+n} + x_i \right)^2}$$

30 where  $x_i$  = TIE;  $N$  = number of samples;  $\tau_0$  = sample period;  $\tau$  = observation interval =  $n\tau_0$ .

**[0025]** To determine the phase noise transfer characteristic of a device, the test signal with a TDEV characteristic is input to a device, and the output phase noise is measured.

**[0026]** TDEV may also be expressed as the power spectral density of phase ( $S_\phi$ ) and time interval error ( $S_x$ ), where time interval error  $x(t) = \phi(t) / (2\pi v_{\text{norm}})$ . From ITU Standard II.3/G.810, this gives:

$$\text{TDEV}(\tau) = \sqrt{\frac{2}{3(\pi v_{\text{norm}} n)^2} \int_0^{f_h} S_\phi(f) \frac{\sin^6(\pi n \tau_0 f)}{\sin^2(\pi \tau_0 f)} df}$$

where  $v_{\text{norm}}$  = nominal frequency of reference with wander and  $S_\phi(f)$  and  $S_x(f)$  are related by the following equation:

$$S_x(f) = \frac{1}{(2\pi v_{\text{norm}})^2} S_\phi(f)$$

Hence:

$$\text{TDEV}(\tau) = \sqrt{\frac{8}{3n^2} \int_0^{f_h} S_x(f) \frac{\sin^6(\pi n \tau_0 f)}{\sin^2(\pi \tau_0 f)} df}$$

As the largest frequency is  $f = 10$  Hz and the largest  $\tau_0 = (1 / 30)$  ms, then  $\pi \tau_0 f \leq 1.047$ , and  $n \sin(\pi \tau_0 f) \approx n \pi \tau_0 f = \pi \tau f$ . Hence:

$$\text{TDEV}(\tau) = \sqrt{\frac{8}{3} \int_0^{f_h} S_x(f) H^2(\tau, f) df}$$

where:

$$H(\tau, f) = \sqrt{\frac{8}{3} \frac{\sin^3(\pi \tau f)}{(\pi \tau f)}}$$

**[0027]** The squared transfer function  $H^2(\tau, f)$  is shown in FIG. 1 for varying frequency and a constant  $\tau$ . It can be seen that the function  $H^2(\tau, f)$  has peaks at a frequency of  $0.42/\tau$ . Thus, TDEV can be expressed as a bandpass filter centered on a frequency of  $0.42 / \tau$ . An example input TDEV noise characteristic is shown in FIG. 3, with TDEV changing by powers of  $\tau$  between different values of  $\tau$ . Such profiles are specified by the ITU for noise signals to be used for testing networks.

**[0028]** The transfer function squared  $H^2(\tau, f)$  is shown in FIG. 2 for varying  $\tau$  for a single frequency tone, from which it can be seen that the response is the same as that shown in FIG. 1. It is therefore possible to use a sine wave with an arbitrary frequency  $f$  to produce a sequence to modulate a clock signal.

5 This will produce the response shown in FIG. 2. The magnitude of the TDEV response is in direct proportion to the amplitude of the sine wave used to modulate the clock signal.

**[0029]** Accordingly, sine waves of different frequencies can be used to produce a sequence, which will modulate the clock signal. The resulting TDEV  
10 response will be the combination of the individual sine wave TDEV responses. The required TDEV response can be obtained by altering the relative gains and frequencies of the sine waves. A method for determining the parameters of the sine waves will now be described with reference to FIG. 8, which is a schematic flowchart showing the main steps involved.

15 **[0030]** When a new TDEV profile is provided 10, the required range of frequencies of the sine waves can be determined 11 by considering the extremal  $\tau$  limits for a specific mask. An ITU mask will specify upper and lower limits for  $\tau$  (as shown in FIG. 3). In order to provide full TDEV coverage, the frequency range for the required tones is therefore chosen to be one decade  
20 higher than the highest bandpass filter centre frequency ( $0.42/\tau$ ) associated with the mask and to be one decade lower than the lowest bandpass filter centre frequency associated with the mask.

**[0031]** By choosing an appropriate tone density for the frequency range, the number of tones  $N$  (frequencies) needed can be determined 12 and stored 13.  
25 The tone density between the maximum and minimum tone frequencies has to be such that the resulting TDEV noise signal meets the ITU mask requirement. Experimentation has shown that a tone density of 40 tones/decade in which the tone spacing is arranged geometrically is sufficient to provide good coverage of a mask yielding all the frequency values ( $f_i$ ) 14. The frequency values  $f_i$  for each  
30 of the tones are then stored 15.

**[0032]** Having selected the frequency values  $f_i$  of all the tones, the amplitude  $A_i$  of the tones is obtained 16 by iteratively fitting amplitudes to all the tones and selecting the amplitude for a given tone which produces the closest fit to the mask. A computer program, such as a limit fit program can be utilised to

generate the actual gain values of the sine waves which results in a wander noise profile (mask) as specified by ITU. This program attempts to generate a TDEV response between given limits using sine waves. For example, an arbitrary set of amplitude values combine to give a TDEV characteristic. This  
5 TDEV characteristic is compared with a chosen mask and its limits. When the TDEV response first breaks the limits, the sine waves after this break are adjusted to allow the response to stay within the mask. The output of the limit fit algorithm yields all the amplitude values ( $A_i$ ), which are then stored 17.

**[0033]** The generated noise will have a characteristic within limits specified by  
10 ITU of the ideal profile. The time distribution of the wander noise has a statistical profile that can be adjusted by changing the relative phases of the sine waves. This can be achieved by Monte Carlo Analysis and produces 18 all the tone phase values ( $\theta_i$ ). For example, the skewness and kurtosis of the generated noise can be shaped to approximate gaussian noise by adjusting the individual  
15 phase values of the tones. Gaussian noise has a skewness value of 0 and a kurtosis value of 3.0. A Monte Carlo analysis, whereby a random set of phases for all the tones is successively applied in a procedure which compares the resulting skewness and kurtosis values against the required values, can be used. The procedure is stopped when the skewness and kurtosis values are  
20 within the required limits and no significant improvement is obtained by further iteration. The phase values  $\theta_i$  are then stored 19. FIG. 4 shows the skewness and kurtosis figures for a phase value of zero, before the Monte Carlo analysis and FIG. 5 shows the corresponding result following a Monte Carlo analysis, in which the skewness and kurtosis values are more typical for gaussian noise (i.e.  
25 closer to a skewness value of 0 and a kurtosis value of 3.0 even for low sample numbers) than those exhibited in FIG. 4.

**[0034]** An apparatus 1 for generating wander noise according to one embodiment of the present invention is shown schematically in FIG. 6. As shown, the apparatus 1 includes a processor 2, for example a Digital Signal  
30 Processor (DSP), which provides a noise generation function 3 and an adder function 4. The processor 2 receives an input 6 which comprises a selection of a particular TDEV characteristic (mask) setting that is required to be used to generate the wander noise. The selection corresponds to a frequency profile that has been predetermined and for which frequency, amplitude and phase

values for a number of sine wave tones are stored in a memory 5. The processor 2 reads the which frequency, amplitude and phase values for the tones from the memory and generates a digital noise signal  $n(k)$  by the addition of these sine waves according to the equation:

$$n(k) = \sum_{i=1}^N A_i \sin(2\pi f_i k + \theta_i)$$

5

where  $N$  = number of tones,  $A_i$  is the amplitude value for the particular tone  $i$ ,  $f_i$  is the frequency value for the particular tone  $i$ ,  $\theta_i$  is the phase value for the particular tone  $i$ , and  $k$  is the time index of the noise sample.

**[0035]** A Frequency Tuning Word value ( $f_0$ ) which is the centre frequency for the mask is also input 7 to the processor 2 and is added by the adder function 4 to the noise sequence  $n(k)$  to produce a centred digital noise signal  $y(k)$ . This centred digital noise signal is output from the processor 2 to a direct digital synthesizer 8, where it is converted to the required wander noise signal and provided at output 9 of the apparatus 1.

15 **[0036]** Returning to FIG. 8, the method of operation of the apparatus of FIG. 7 is shown schematically for generating wander noise 20. As shown, a particular profile is first selected 21, and the number of tones ( $N$ ), frequency values ( $f_i$ ), amplitude values ( $A_i$ ) and phase values ( $\theta_i$ ) are obtained by the processor 2 from the memory 5 where they were previously stored 13 - 19. The digital noise signal  $n(k)$  is then calculated 23. After the centre frequency  $f_0$  value is obtained 24, the centred digital noise signal  $y(k)$  is calculated 25 and then the wander noise signal is synthesized 26.

25 **[0037]** As shown FIG. 7, such a wander signal 27 is a satisfactory approximation of the desired simulated TDEV characteristic 28. The simulated TDEV mask is the same as that shown in FIG. 3.

**[0038]** It will be appreciated that although only one particular embodiment of the invention has been described in detail, various modifications and improvements can be made by a person skilled in the art without departing from the scope of the present invention. For example, although the tone spacing has been described as being geometrical, it will be appreciated that arithmetic or other tone spacings could be used.

30
